Abstract

11β-Hydroxylase (hCYP11B1) and aldosterone synthase (hCYP11B2) are closely related isozymes with distinct roles in cortisol and aldosterone production respectively. Aldosterone synthase catalyzes the final step in aldosterone biosynthesis and is expressed only in the zona glomerulosa of the normal adrenal. 11β-Hydroxylase catalyzes the final reaction in the production of cortisol and is expressed at higher levels in the zona fasciculata. The mechanisms causing differential expression of these genes are not well defined. Herein, we demonstrate contrasting roles for the orphan receptor steroidogenic factor-1 (SF-1) in the regulation of human (h) CYP11B1 and hCYP11B2. Human NCI-H295R (H295R) or mouse Y-1 cells were transiently transfected with luciferase reporter constructs containing 5′-flanking regions of hCYP11B1, hCYP11B2, human 17α-hydroxylase (hCYP17), human cholesterol side-chain cleavage (hCYP11A1) or mouse (m) cyp11b1 (mcyp11b2). Co-transfection of vectors encoding SF-1 increased expression of hCYP11B1, hCYP11A1 and hCYP17 constructs, but inhibited hCYP11B2 reporter activity. Murine, bovine and human SF-1 were unable to increase transcription of hCYP11B2 in H295R cells. Both hCYP11B2 and mcyp11b2 promoter constructs were inhibited similarly by human SF-1. In mouse Y-1 cells, reporter expression of hCYP11B2 and mcyp11b2 was very low compared with hCYP11B1 constructs, suggesting that this adrenal cell model may not be appropriate for studies of CYP11B2. Electrophoretic mobility shift assay demonstrated that SF-1 interacted with an element from both hCYP11B1 and hCYP11B2. However, mutation of this element, termed Ad4, did not prevent agonist stimulation of hCYP11B2 by angiotensin II or forskolin but blocked activity of hCYP11B1. In some, but not all, reports of genetic linkage analysis, a naturally occurring single nucleotide polymorphism within the Ad4 element of hCYP11B2 (−344C/T) has been associated with cardiovascular disease. Herein, we have demonstrated that this polymorphism influenced binding of SF-1 in electrophoretic mobility shift assays, with the C allele binding SF-1 more strongly than the T allele. However, when hCYP11B2 constructs containing these alleles were transfected into H295R cells, there was no difference in agonist-stimulated expression or the response of either reporter construct to co-expression with human SF-1. Taken together, these data suggest that SF-1 and the Ad4 element are not major regulators of adrenal hCYP11B2 gene expression. Thus far, hCYP11B2 is the first steroid hydroxylase gene which is not positively regulated by SF-1.

Introduction

The adrenal cortex is the site of synthesis of the potent mineralocorticoid, aldosterone, and the glucocorticoid, cortisol. CYP11B2 (aldosterone synthase), which is expressed only within the zona glomerulosa of the adrenal cortex, is responsible for converting deoxycorticosterone to aldosterone (Kawamoto et al. 1990, Curnow et al. 1991, Domalik et al. 1991, Ogishima et al. 1992, LeHoux et al. 1995, Pascoe et al. 1995). On the other hand, CYP11B1 (11β-hydroxylase) appears to be expressed predominantly in the fasciculata of the adrenal, where (in humans) it is responsible for the
conversion of deoxycortisol to cortisol (Kawamoto et al. 1990, Curnow et al. 1991, Erdmann et al. 1995). In humans and rodents, the capacity of the adrenal cortex to differentially produce mineralocorticoid and glucocorticoid relies to a large extent on the zonal expression of the human (h) CYP11B isoforms which, in turn, ultimately depends upon the various cis-elements and trans-acting factors that control gene transcription.

The cis-elements controlling zone-specific expression lie mainly in the 5′-flanking regions of these genes. This has been demonstrated by genetic studies of individuals with glucocorticoid-suppressible hyperaldosteronism (GSH), an inherited form of hypertension in which CYP11B2 is expressed in a manner similar to the normal pattern of expression of CYP11B1. In GSH, hCYP11B2 is regulated by adrenocorticotropin (ACTH) via cAMP-dependent signaling and it is expressed in the zona fasciculata. This disorder is caused by intergenic recombinations that juxtapose the 5′-flanking region and the first 2–4 exons of CYP11B1 with coding sequences of CYP11B2 (Lifton et al. 1992a,b, Pascoe et al. 1992).

Several conserved cis-elements have been identified within the 5′-flanking region of CYP11B genes of different species (Rainey 1999). DNase I footprint analysis of the bovine (b) CYP11B 5′-flanking DNA demonstrated several regions, termed Ad1 through Ad6, that bound nuclear proteins (Morohashi et al. 1992a, Takayama et al. 1994). Similar sequences have been observed in the hCYP11B1 (Wang et al. 2000) and hCYP11B2 (Clyne et al. 1997) genes. Of these elements, Ad1 and Ad4 are required for cAMP-induced and basal transcription respectively of hCYP11B1 (Wang et al. 2000). The Ad4 sequence (AAGGCT/CC) is a nuclear receptor half-site which binds steroidogenic factor-1 (SF-1, also called Ad4BP) (Ikeda et al. 1995, Morohashi & Omura 1996), a monomeric orphan nuclear receptor that is required for the co-ordinated development and function of the adrenals and gonads. In the adult adrenal and gonad, SF-1 is essential for full expression of every steroid hydroxylase gene studied thus far, including cholesterol side-chain cleavage enzyme (CYP11A1) (Clemens et al. 1994, Liu & Simpson 1997), 11β-hydroxylase (CYP11B1) (Wang et al. 2000), 21-hydroxylase (CYP21) (Ikeda et al. 1993), 17α-hydroxylase/17,20 lyase (CYP17) (Givens et al. 1994, Bakke & Lund 1995) and aromatase (CYP19) (Michael et al. 1995). It is also required for full expression of other key components of steroidogenesis such as steroidogenic acute regulatory protein (Sugawara et al. 1997), 3β-hydroxysteroid dehydrogenase type II (Leers-Sucheta et al. 1997) and the ACTH receptor (Cammas et al. 1997, Marchal et al. 1998).

However, the role of SF-1 in expression of hCYP11B2 is uncertain. Studies of a series of reporter constructs with serial deletions of the 5′-flanking region of hCYP11B2 suggested that the Ad4 element was not essential for expression (Clyne et al. 1997). On the other hand, a naturally occurring single nucleotide polymorphism involving this site (−344C/T) has been implicated as affecting aldosterone levels, blood pressure, heart size and risk of myocardial infarction, although none of these associations has been consistently observed in all studies (White & Slutsker 1995, Brand et al. 1998, Hautanen et al. 1998, Kupari et al. 1998, Davies et al. 1999, Hautanen et al. 1999, Schunkert et al. 1999, Tamaki et al. 1999, Patel et al. 2000, Ylitalo et al. 2000).

The current study was undertaken to clearly define the role of SF-1, the Ad4 element and the Ad4 polymorphism in hCYP11B2 expression. Our results have demonstrated that, while SF-1 appears to play a critical role in hCYP11B1 transcription through interactions with the Ad4 element, this element and SF-1 do not play major roles in adrenal cell hCYP11B2 gene expression. Thus, hCYP11B2 is apparently the first of the human steroid hydroxylase genes which does not require SF-1 for full expression. The differences in the cis-elements that regulate hCYP11B1 and hCYP11B2 transcription may help to explain the differential expression of these isozymes within the adrenal cortex.

Materials and methods

Preparation of reporter constructs and expression vectors

A transient expression system using a luciferase reporter gene was used to characterize the Ad4/SF-1 binding site present in the hCYP11B1 (Wang et al. 2000), hCYP11B2 (Clyne et al. 1997) and mouse (m) cyp11b2 (Bogerd et al. 1990) gene promoters. The hCYP11B1 (pB1–1102), hCYP11B2 (pB2–1521) and mCyp11b2 (pmB2–1500) constructs
used in our study contained 1102, 1521 and 1500 bp 5′-flanking DNA respectively and were cloned into the promoterless pGL3–Basic luciferase reporter plasmid (Promega, Madison, WI, USA). Unless otherwise indicated, experiments involving the CYP11B2 plasmids refer to constructs containing the C allele at position –344 relative to the translation start site. For generation of the hCYP11B2 Ad4 mutant construct, the sequence 5′-CCAAGGCCC-3′ (–344/–336) was changed to 5′-CcgAattCC-3′ by site-specific mutagenesis (Stratagene, La Jolla, CA, USA) using the primer shown in Table 1. The 5′-flanking region of pSCC-4400 (Hu et al. 1999) was subcloned into the pGL3–Basic vector to generate the hCYP11A1 promoter plasmid, pA1–4400. The preparation of the hCYP17 promoter construct (pC17–1088) has been described previously (Hanley et al. 2001).

The coding sequences of mouse and bovine SF-1 were kindly provided by Keith Parker (University of Texas Southwestern Medical School, Dallas, TX, USA) and Ken-ichirou Morohashi (National Institute for Basic Biology, Okazaki, Japan) respectively. Human SF-1 was provided by Meera Ramayya (University of Washington, Seattle, WA, USA). Coding sequences for all three SF-1 plasmids were excised from their vectors and subcloned into the pRc/RSV expression plasmid (Invitrogen, Carlsbad, CA, USA). Keith Parker also supplied the mouse pmB2–1500 construct.

**Cell culture and transfection assay**

NCI-H295R (H295R) human adrenocortical tumor cells or mouse Y-1 adrenal tumor cells were cultured in Dulbecco’s modified Eagle’s/Ham’s F12 (DME/F12) medium (Gibco-BRL, Gaithersburg, MD, USA) supplemented with 2% Ultroser G (BioSepra SA, Villeneuve la Garenne Cedex, France), 1% ITS (Insulin Transferrin Selenium) Plus (Collaborative Research, Bedford, MA, USA) and antibiotics. We have previously described the use of the H295R and Y-1 cell lines to study the human CYP11B1 and CYP11B2 reporter constructs (Clyne et al. 1996, 1997, Wang et al. 2000). For transfection experiments, cells were subcultured onto 12-well culture dishes at a density of 300 000 cells/well (H295R) or 150 000 cells/well (Y-1) for use 36 h later. Transfection was carried out using 2·0 µl Fugene (Roche, Indianapolis, IN, USA) and 1·0 µg reporter plasmid DNA in DME/F12 medium (1·1 ml) for 6 h at 37°C. For co-transfection experiments, various amounts of expression plasmids were included in the transfection reaction, and the total amount of DNA was kept constant by addition of carrier DNA (empty expression vector). Following transfection, cells were incubated with 2·0 µl Fugene (Roche, Indianapolis, IN, USA) and 1·0 µg reporter plasmid DNA in DME/F12 medium (1·1 ml) for 6 h at 37°C. For co-transfection experiments, various amounts of expression plasmids were included in the transfection reaction, and the total amount of DNA was kept constant by addition of carrier DNA (empty expression vector). Following transfection, cells were incubated with 2·0 ml low serum medium (DME/F12 medium containing 0·1% Ultroser G and antibiotics) for 18–24 h to allow for recovery and expression of foreign DNA. Where indicated, transfected cells were treated with agonists for 6 h. Cells were then lysed and assayed for activity using the luciferase assay system (Promega).

**Electrophoretic mobility shift assay (EMSA)**

H295R nuclear extracts were prepared by the method of Schreiber et al. (1989). To prepare radiolabeled probe, double-stranded oligonucleotides (25 pmol) containing 5′ protruding ends were labeled, by fill-in reaction, using [α-32P]dCTP and

The hCYP11B2 reporter construct with mutated (m) Ad4/SF-1 bases (lowercase letters) was produced using the indicated primer. EMSAs were performed using wild-type (wt) Ad1 and wt Ad4 oligonucleotides corresponding to the indicated sequence in either hCYP11B1 or hCYP11B2. The hCYP11B2 Ad4 polymorphic oligonucleotides are indicated (C or T).
Moloney murine leukemia virus reverse transcriptase at 37 °C for 30 min (Gibco-BRL). Five micrograms of nuclear extract and each radiolabeled probe (40,000 d.p.m.) were incubated at room temperature for 20 min in 20 µl reaction mixture (20 mM HEPES (pH 8.0), 80 mM KCl, 1 mM EDTA, 10% glycerol, 1 mM dithiothreitol, 0.5 mg/ml bovine serum albumin and 0.075 mg/ml poly dI-dC as non-specific competitor). For competition analysis, reaction mixtures containing various amounts of non-radiolabeled oligonucleotide were added simultaneously with probe. The resulting DNA/protein complexes were then separated from free probe by electrophoresis using a 4% high ionic strength native polyacrylamide gel with 1/2 Tris–glycine running buffer. The gel was dried and visualized following autoradiography at −70 °C for 24 h. Human SF-1 was prepared using a Promega in vitro transcription/translation system.

The hCYP11B1- and hCYP11B2-specific Ad1 and Ad4 oligonucleotide sequences that were used for EMSA are listed in Table 1.

**Statistical analsysis**

Statistical comparison of means of three or more samples was accomplished by ANOVA. Significance was accepted at the 0.05 level of probability.

**Results**

**Comparison of the effects of SF-1 upon various steroidogenic enzymes**

Several steroidogenic P450 genes, including hCYP11B1 and hCYP11B2, contain consensus binding sites for SF-1 in their proximal 5′-flanking DNA. In order to examine the effects of SF-1 upon various steroidogenic enzymes, we co-transfected H295R cells with reporter constructs containing the 5′-flanking DNA of hCYP11A1 (pA1–4400), hCYP11B1 (pB1–1102), hCYP11B2 (pB2–1521) or hCYP17 (pC17–1088) along with a β-galactosidase expression vector. As shown in Fig. 2, the hCYP11B1 promoter was activated by SF-1 in a concentration-dependent manner; the hCYP11B2 promoter decreased by greater than 50% when compared with basal levels of hCYP11B2 gene expression (Fig. 1). These data suggest that the regulation of hCYP11B2 transcription is quite different from that of the other cytochrome P450 genes involved in steroid metabolism. The following experiments were designed to determine if indeed hCYP11B2 represents the first steroidogenic cytochrome P450 gene that is not positively regulated by SF-1.

**Concentration-dependent effects of SF-1 on hCYP11B1 and hCYP11B2 reporter gene activity**

In order to clarify the role of SF-1 in the transcriptional regulation of the two hCYP11B genes, we co-transfected H295R cells with pB1–1102 or pB2–1521 and increasing concentrations of an expression vector containing the coding sequence for human SF-1. As shown in Fig. 2, the hCYP11B1 promoter was activated by SF-1 in a concentration-dependent manner;
activity increased to 10-fold above basal levels when cells were co-transfected with 1 µg SF-1 plasmid. In contrast, we observed a reduction of luciferase activity by 44% for the hCYP11B2 reporter at 1 µg SF-1 expression plasmid.

The response of hCYP11B1 and hCYP11B2 to mouse, bovine and human SF-1

There have been conflicting reports in the literature regarding the importance of the Ad4 element in the transcriptional regulation of the CYP11B2 gene (Bogerd et al. 1990, Clyne et al. 1997, Lehoux & Lefebvre 1998). We therefore compared the ability of SF-1 from three different species to transactivate the human CYP11B1 or CYP11B2 gene promoters. As shown in Fig. 3, mouse, bovine and human SF-1 proteins were able to activate the hCYP11B1 promoter plasmid but failed to stimulate hCYP11B2.

Comparison of the effects of SF-1 on human CYP11B2 and mouse cyp11b2 reporter constructs

Initial transfection studies of the mouse cyp11b2 promoter in mouse Y-1 adrenal tumor cells suggested that the Ad4/SF-1 element was important for basal transcription (Bogerd et al. 1990). Therefore, we compared the ability of human SF-1 to stimulate human or mouse cyp11b2 reporter constructs in both human H295R and Y-1 adrenal cells (Fig. 4). SF-1 failed to stimulate reporter activity for either the mouse or human CYP11B2 promoter constructs in the human H295R cell line. SF-1 did slightly induce human (2-fold) and mouse (1.25-fold) CYP11B2 reporter construct activity in mouse Y-1 cells. However, the basal activity of the hCYP11B2 reporter constructs in Y-1 cells is only 3% of the basal activity observed with the hCYP11B1 promoter vector, whereas in H295R cells the basal activity of the hCYP11B2 reporter is generally 1.5- to 2-fold greater than that of hCYP11B1 (data not shown).
The role of the Ad4 element in regulating hCYP11B1 and hCYP11B2 transcription

There is good evidence suggesting an important role for the Ad4 element in bCYP11 and hCYP11B1 transcription (Morohashi et al. 1992b, Wang et al. 2000). In order to determine if differences in transcriptional regulation of the hCYP11B genes are due to binding properties of SF-1 to the hCYP11B1 and hCYP11B2 Ad4 consensus sequence, EMSA was carried out using both Ad4 sequences (Fig. 5). In the presence of H295R nuclear extract and the specific Ad4 oligonucleotides for hCYP11B1 or hCYP11B2, at least two major DNA/protein complexes were detected. One of the complexes (C1) was displaced from both labeled Ad4 sequences by the addition of a 100-fold molar excess of non-radiolabeled competitor but failed to be displaced by a non-specific oligonucleotide (Ad1). These results indicated that the C1 complex represented a specific protein/DNA interaction. Additionally, in vitro translated SF-1 protein formed a complex with both of the Ad4 oligonucleotides; these SF-1/oligo complexes co-migrated with the C1 band present in both the hCYP11B1 Ad4 and hCYP11B2 Ad4 elements.

Recently, we reported that mutation of the Ad4 consensus sequence of hCYP11B1 reduced basal,
dibutyryl cyclic AMP-stimulated and SF-1-transactivated reporter gene activity in H295R cells (Wang et al. 2000). In contrast, mutation of the Ad4 consensus sequence in the hCYP11B2 luciferase reporter plasmid had little effect on basal, angiotensin II (Ang II)- or forskolin-induced, or SF-1-stimulated activity when transfected into these cells (data not shown). Thus, the Ad4 element does not appear to be important for transcriptional regulation of hCYP11B2. These results confirmed and extended our previous observations using reporter constructs carrying serial deletions of the 5′-flanking region of hCYP11B2 (Clyne et al. 1997).

**Analysis of the single nucleotide polymorphism located within the Ad4 element of hCYP11B2**

Although these results demonstrated that the Ad4 element did not play a major role in regulating hCYP11B2 expression in H295R cells, previous reports had suggested that a single nucleotide polymorphism in the Ad4 element located 344 nucleotides 5′ to the translation initiation site of the gene might have important effects in vivo (White & Slutsker 1995, Brand et al. 1998, Hautanen et al. 1998, 1999, Kupari et al. 1998, Davies et al. 1999, Schunkert et al. 1999, Tamaki et al. 1999, Patel et al. 2000, Ylitalo et al. 2000). This polymorphism (−344C/T) is located within the AAGGC(C/T)C core sequence of the Ad4/SF-1 binding site. In order to assess the relative binding affinities of the C and T alleles, synthetic oligonucleotides containing these alleles were radiolabeled and used in EMSA (Fig. 6). When incubated in the presence of increasing concentrations of in vitro synthesized SF-1 protein as indicated. The position of the band corresponding to SF-1 is indicated by an arrow to the left of the Figure.

**Discussion**

SF-1 plays a pivotal role in the development of the adrenals and gonads. In addition, the expression of
several of the enzymes involved in steroid hormone biosynthesis relies heavily on SF-1 for maximal gene transcription. However, the exact role of SF-1 in the transcription of each of the individual cytochrome P450 genes that encode the steroid-metabolizing enzymes is less understood. Herein, we have used promoter constructs prepared using the 5’-flanking DNA from the human CYP11A1, CYP17, CYP11B1 and CYP11B2 genes. Our data suggest that co-expression of SF-1 is very effective at activating transcription of CYP11A1, CYP17 and CYP11B1. However SF-1 does not appear to play an important role in the transcription of hCYP11B2.

Role of SF-1 in hCYP11B2 expression

There is a relatively high degree of sequence similarity between the first 400 bases located in the 5’-flanking regions of hCYP11B1 and hCYP11B2. Both promoters have identifiable consensus cis-elements that were first characterized in the hCYP11B gene (Morohashi et al. 1992a, Takayama et al. 1994, Rainey 1999). Within the Ad4 elements of hCYP11B1 and hCYP11B2, 10 out of 11 nucleotide bases are identical. Since hCYP11B1 is strongly up-regulated by SF-1 through the Ad4 element, the failure of SF-1 to stimulate CYP11B2 transcription – instead of its inhibition of reporter expression – seems surprising. Because CYP11B2 is unique among genes for steroidogenic enzymes in its negative response to SF-1, it is important to exclude trivial explanations for these observations. There could be a non-specific effect of the carrier vector on the promoter constructs. This is unlikely because the amount of DNA was kept constant in all transfections by the addition of empty expression vector. The inhibition could be a collateral effect of the specific expression vector used in our studies. This is also unlikely because the inhibition was observed when SF-1 was co-transfected in expression vectors driven by either RSV (pRc/RSV) or CMV (pcDNA 3·1) promoter (data not shown). The inhibition could be a squelching phenomenon related to the concentrations of SF-1 plasmid used in the study. While this is possible, the highest concentration used for co-transfection (1 µg/ml) was highly effective at stimulating hCYP11B1 as well as hCYP17 and hCYP11A1 promoter constructs. Another possibility could be an effect related to the species of SF-1 used in the expression vector. We tested human, bovine and mouse SF-1 and saw similar effects in each case. It is also possible that these results might
apply only to the human CYP11B2 gene, but we obtained similar results with both human and mouse reporter constructs. Finally, while the inhibitory effect of SF-1 on hCYP11B2 reporter activity is surprising, there is a recent study suggesting that SF-1 does have a repressor domain (Ou et al. 2001). Further studies will be needed to determine if the inhibitory effect of SF-1 co-expression represents a physiologic effect that might occur in vivo.

The different results observed in H295R and Y-1 cells deserve comment. There were dramatic differences between the basal levels of reporter activity of hCYP11B1 and hCYP11B2 in transfected Y-1 cells; the activity of the hCYP11B2 reporter was only 3% of the activity observed for hCYP11B1. In contrast, basal levels of hCYP11B2 expression exceeded those of hCYP11B1 in transfected H295R cells. These results suggest that the Y-1 cell line may have adopted a phenotype similar to fasciculata cells, which express only low levels of hCYP11B2. In contrast, we have previously shown that H295R cells produce aldosterone and also express hCYP11B2 mRNA, which can be induced by Ang II and K+ treatment (Bird et al. 1998, Hautanen et al. 1996, Pezzi et al. 1997). In that regard, the H295R cells may be a more appropriate in vitro model system than mouse Y-1 cells for attempting to define the cis- and trans-acting factors that control the regulation of hCYP11B1 and hCYP11B2 gene expression. Presumably, the inhibition of hCYP11B2 by SF-1 in H295R cells, and the slight stimulation of the same construct by SF-1 in Y-1 cells, are due to the differences in the type and concentration of specific binding proteins (co-repressors or co-activators) present or absent in each cell type. Alternatively, it is conceivable that transcription factors needed for SF-1 to activate hCYP11B2 transcription are not present in the H295R cells. This concern is lessened by the fact that the H295R cells increase expression of hCYP11B2 mRNA following treatment with Ang II and K+.

Role of the −344C/T polymorphism

Several reports have associated the −344C/T polymorphism with variations in aldosterone secretion, blood pressure and other cardiovascular parameters (White & Slutsker 1995, Brand et al. 1998, Hautanen et al. 1998, 1999, Kupari et al. 1998, Davies et al. 1999, Schunkert et al. 1999, Tamaki et al. 1999, Patel et al. 2000, Ylitalo et al. 2000), and we found clear allelic differences in the binding of SF-1 to the polymorphic Ad4 element. Thus, we felt it was possible that this polymorphism could modify the response of this gene to SF-1 and explain the previously noted associations. However, plasmids containing the two alleles were expressed at similar levels under both basal and forskolin-stimulated conditions, and these plasmids were equally repressed when co-transfected with SF-1 expression plasmid. The small allelic difference in stimulation by Ang II is of uncertain significance. It is possible that this polymorphism has additional effects in vivo that cannot be modeled by reporter constructs in H295R cells, either because these effects require additional, and as yet unidentified, cis-elements within hCYP11B2, or because H295R cells lack necessary transcriptional factors. Alternatively, the observed in vivo associations may reflect genetic linkage disequilibrium between the −344C/T polymorphism and other polymorphisms elsewhere in or near hCYP11B2. Indeed, the −344C/T polymorphism is in linkage disequilibrium with a gene conversion in intron 2 of the hCYP11B2 gene (White & Slutsker 1995) and also with a missense mutation, R173K (Mulatero et al. 2000).

The genes that encode the hCYP11B isozymes have clearly evolved distinct mechanisms to control transcription as indicated by their differential expression within the adrenal cortex. However, few studies to date have directly compared the mechanisms regulating these promoters. Herein, we have demonstrated that these genes vary dramatically in their requirement for SF-1, a transcription factor that has been proposed to be necessary for expression of most, if not all, cytochrome P450s involved in steroidogenesis. It is tempting to hypothesize that the lack of expression of hCYP11B2 in the zona fasciculata is, in part, due to the lack of sensitivity to SF-1. The contrasting requirements for SF-1 provide new insight into the differential regulation of these two closely related genes.
